

# Domain structure of ultrathin ferromagnetic elements in the presence of Dzyaloshinskii-Moriya interaction

Cyrill B. Muratov\*      Valeriy V. Slastikov†

September 6, 2016

## Abstract

Recent advances in nanofabrication make it possible to produce multilayer nanostructures composed of ultrathin film materials with thickness down to a few monolayers of atoms and lateral extent of several tens of nanometers. At these scales, ferromagnetic materials begin to exhibit unusual properties, such as perpendicular magnetocrystalline anisotropy and antisymmetric exchange, also referred to as Dzyaloshinskii-Moriya interaction (DMI), because of the increased importance of interfacial effects. The presence of surface DMI has been demonstrated to fundamentally alter the structure of domain walls. Here we use the micromagnetic modeling framework to analyse the existence and structure of chiral domain walls, viewed as minimizers of a suitable micromagnetic energy functional. We explicitly construct the minimizers in the one-dimensional setting, both for the interior and edge walls, for a broad range of parameters. We then use the methods of  $\Gamma$ -convergence to analyze the asymptotics of the two-dimensional magnetization patterns in samples of large spatial extent in the presence of weak applied magnetic fields.

## 1 Introduction

The exploding amount of today's digital data calls for revolutionary new high density, fast and long-term information storage solutions. Spintronics is one among the emerging fields of nanotechnology offering a great promise for information technologies, whereby information is carried and processed, using the electron spin rather than its electric charge [1, 3, 44, 54]. It brings about many opportunities for creating the next generation of devices combining spin-dependent effects with conventional charge-based electronics. Despite being a relatively new field of applied physics, it has already firmly established its presence in everyday life through the development of new magnetic storage devices. The discovery of giant magnetoresistance (GMR), for which A. Fert and P. Grünberg were awarded the

2007 Nobel Prize in Physics, allowed an ability to “read” the magnetization states of a ferromagnet through electric resistance measurements. This effect has been used in GMR-based spin valves, which transformed magnetic hard-disk drive technology, leading to increases in storage density by several orders of magnitude. Yet, the GMR magnetic storage technology has already been superseded by novel spin-dependent devices based on the effect of tunneling magnetoresistance (TMR), another exciting development in the field of spintronics [3].

Recent discoveries of new physical phenomena that become prominent at nanoscale open up a possibility of unprecedented data storage densities and read/write speeds. These include spin transfer torque (STT), chiral domain walls and magnetic skyrmions, spin Hall effect, spin Seebeck effect, electric field control of the magnetic properties, etc. (see, e.g., [3, 8, 11, 18, 35, 41, 51]). The ability to manipulate the magnetization, using electric currents suggests novel designs for magnetic memory. One popular concept is the so-called racetrack memory [3, 43], which uses a two-dimensional array of parallel nanowires where magnetic domains – “bits” – may be read, moved, and written through an application of a spin current. Another promising type of memory and logic devices is based on storing and manipulating the data bits, using magnetic skyrmions, rather than magnetic domain walls. The existence of magnetic skyrmions was predicted theoretically more than twenty-five years ago [5, 6], but their experimental observations are much more recent [24, 41, 52]. The topological stability, small size and extremely low currents and fields required to move magnetic skyrmions make them natural candidates for the use in spintronic memory and logic devices [18, 52, 53].

A successful design of novel spintronic devices that make use of magnetic domain walls or skyrmions is strongly dependent on a deep theoretical understanding of static and dynamic behaviors of the magnetization in magnetic nanostructures. The manipulation and control of magnetic domain walls and topologically protected states (e.g., magnetic vortices and skyrmions) in ferromagnetic nanostructures has been the subject of extensive experimental and theoretical research (see, e.g., [7, 9, 11, 22, 45, 47, 50]; this list is certainly far from complete). Recent advances in nanofabrication techniques [48] have lead to the production of ultrathin films with thickness down to several atomic layers and a lateral extent down to tens of nanometers. These ultrathin magnetic films and multilayer structures often exhibit unusual magnetic properties, attributed to an increased importance of interfacial effects. The most important features of these ultrathin magnetic structures include the appearance of perpendicular magnetic anisotropy [23, 27] and the Dzyaloshinskii-Moriya interaction (DMI) [15, 39]. The latter is closely related to reflection symmetry breaking in such films and leads to emergence of magnetization chirality [17, 25, 50].

The experimental discovery of the symmetry breaking Dzyaloshinskii-Moriya interaction in ferromagnetic multilayers has generated a lot of interest in the physics community [4, 24, 46]. There has been a lot of work focusing on the influence of DMI on magnetization configurations within a ferromagnetic sample [4, 45, 50]. One of the interesting features of DMI is its influence on the profile and the dynamic properties of domain

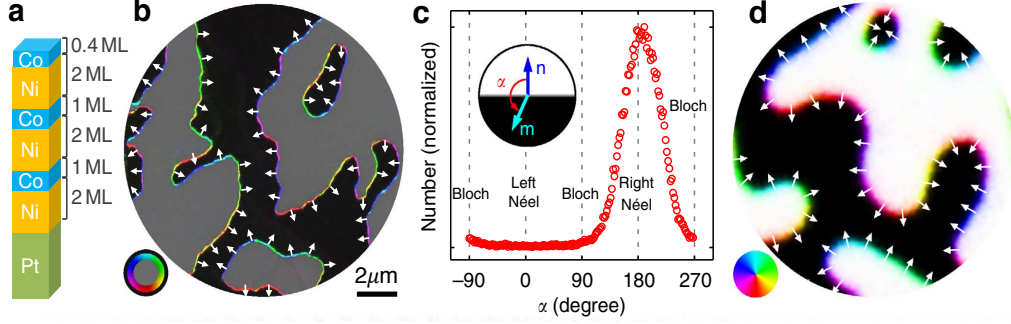

Figure 1: Experimental and numerical observations of chiral domain walls in ultrathin ferromagnetic films in the presence of DMI. (a) The schematics of the multilayer structure. (b) A colormap of the magnetization exhibiting chiral domain walls. (c) A histogram of the in-plane magnetization orientation angle relative to the in-plane normal to the domain wall showing a preferred rotation direction. (d) A comparison to the result of a Monte-Carlo simulation of a discrete spin model. In (b), gray indicates the domains with the magnetization up, black indicates the domains with the magnetization down, and the rest of the colors correspond to the directions of the in-plane component, as shown in the color-wheel. walls [11, 16, 45, 50]. In addition, it is well-known that DMI may be responsible for formation of magnetic skyrmions – topologically protected states with a quantized topological degree observed in ultrathin films [36, 41]. DMI also plays a crucial role in defining the orientation of the domain walls and chiral behavior of the magnetization inside the wall, leading to the formation of a new type of *chiral domain walls*, also referred to as the Dzyaloshinskii walls [50], having rather different properties than the conventional Bloch and Neel walls [26]. For an illustration of chiral domain walls observed experimentally and numerically, see Fig. 1. In a recent theoretical work [45], it was reported that the interplay between DMI and the boundary of an ultrathin ferromagnetic sample is responsible for creating another type of domain walls – *chiral edge domain walls*. These walls play a crucial role in producing new types of magnetization patterns inside a ferromagnet. For instance, in the presence of a transverse applied field, chiral edge domain walls provide a mechanism for *tilting* of an interior domain wall in a ferromagnetic strip [7, 40]. Moreover, they also significantly modify the dynamic behavior of the interior domain wall under the action of current and an applied field [50].

In this paper, we study chiral domain walls in ultrathin ferromagnetic films, using rigorous analytical methods within the variational framework of micromagnetics. Our goal is to understand the formation of chiral interior domain walls and chiral edge domain walls, viewed as local or global energy minimizing configurations of the magnetization, in sam-

ples with perpendicular magnetocrystalline anisotropy in the presence of surface DMI and weak applied magnetic fields. The multi-scale nature of the micromagnetic energy allows for a variety of distinct regimes characterized by different relations between the material and geometric parameters, and makes its investigation a very challenging mathematical problem. Many of these regimes have been investigated analytically, using modern techniques of calculus of variations in the context of various ferromagnetics nanostructures (see, e.g., [14]).

Our starting point is a reduced two-dimensional micromagnetic energy, in which the stray field contributes only a local shape anisotropy term to the leading order (see (2.2) below). This energy gives rise to a non-convex vectorial variational problem, with a non-trivial interplay between the boundary and the interior of the domain due to the DMI term. We seek to understand the formation and structure of the domain walls – transition layers between constant magnetization states – that correspond to minimizers of the micromagnetic energy. The framework for this analysis is provided by the variational methods of the gradient theory of phase transitions [37]. These types of problems have been extensively studied in the mathematical community in both scalar [31, 37, 38, 42] and vectorial [20, 49] settings. The nontrivial influence of the boundary within the gradient theory of phase transitions was investigated in [38, 42].

We begin by investigating the one-dimensional problems on the infinite and semi-infinite domains. Here we provide a complete analytical solution for the global energy minimizers of these one-dimensional problems, see Theorem 1 and Theorem 4, respectively. Our main tool is a careful analysis of the case of equality in the vectorial Modica-Mortola type lower bound for the energy of one-dimensional magnetization configurations. Our analysis yields explicit profiles for one-dimensional chiral interior and edge domain walls. These optimal profiles are used later on in the constructions for the full two-dimensional problem. Our one-dimensional results confirm the physical intuition of [45] for a slightly reduced range of the DMI constants.

We then investigate the full two-dimensional energy in the regime of large domains and small applied fields, using methods of  $\Gamma$ -convergence. After a rescaling, this amounts to a study of the asymptotic behavior of the energy  $E_\varepsilon(\mathbf{m})$  in (4.2) as  $\varepsilon \rightarrow 0$ . We note that our original problem is vectorial, constrained ( $|\mathbf{m}(x)| = 1$ ), and the energy contains linear gradient terms in the interior, as well as boundary terms (after integration by parts), both coming from DMI. Even though the original problem is vectorial – and these are notoriously difficult phase transition problems – we show that one can reduce our problem to a scalar setting by decoupling the behavior of the normal magnetization component  $m_\parallel$ , preferring to be equal to  $\pm 1$ , and the in-plane component  $\mathbf{m}_\perp$ , preferring to be 0, outside the transition layer and proving that the optimal configuration of  $\mathbf{m}_\perp$  is a function of  $m_\parallel$  and the layer orientation. This nontrivial observation significantly simplifies the analysis of the problem and allows us to use the methods developed in [38, 42] to obtain the  $\Gamma$ -limit of the family of micromagnetic energies. The rest of the proof follows the pattern of the gradient theory of phase transitions [37], with some modifications to account for the

vectorial and constrained nature of the problem.

With the above tools, we obtain the  $\Gamma$ -limit, given by (4.3), of the family of energies in (4.2) with respect to the  $L^1$  convergence of  $m_{\parallel}^{\varepsilon}$ . The limit energy is geometric, and its minimizers determine the locations of the chiral domain walls, which are now curves separating the regions in which  $m_{\parallel}^0$  changes sign. As a consequence, we also obtain an asymptotic characterization of the energy minimizers of  $E_{\varepsilon}$  as  $\varepsilon \rightarrow 0$ . Our main result, stated in Theorem 6, indicates that the presence of DMI significantly modifies the magnetization behavior in ultrathin magnetic films by creating both interior and edge chiral domain walls.

The paper is organized as follows. In section 3, we present the solution of the one-dimensional global energy minimization problem for both the interior and boundary chiral domain walls. Then, in section 4 we investigate the full two-dimensional energy (2.2) in the regime of large domains and small applied fields and study the behavior of the family of micromagnetic energies in (4.2) in the limit as  $\varepsilon \rightarrow 0$ . Finally, in section 5 we summarize our findings and discuss several additional modeling aspects of our problem, together with some possible extensions of our analysis.

## 2 Model

We start by considering a ferromagnetic film of thickness  $d$  occupying the spatial domain  $\Omega \times (0, d) \subset \mathbb{R}^3$ , where  $\Omega \subseteq \mathbb{R}^2$  is a two-dimensional domain specifying the shape of the ferromagnetic element. Within the micromagnetic framework [26], the magnetization in the sample is described by the vector  $\mathbf{M} = \mathbf{M}(x, y, z)$  of constant length  $|\mathbf{M}| = M_s$ , where  $M_s$  is referred to as the saturation magnetization. The micromagnetic energy in the presence of an out-of-plane uniaxial anisotropy and an interfacial Dzyaloshinskii-Moriya interaction (DMI) may be written in the SI units in the form [5, 6, 50]

$$\begin{aligned} E(\mathbf{M}) = & \frac{A}{M_s^2} \int_{\Omega \times (0, d)} |\nabla \mathbf{M}|^2 d^3 r + \frac{K}{M_s^2} \int_{\Omega \times (0, d)} |\mathbf{M}_{\perp}|^2 d^3 r - \mu_0 \int_{\Omega \times (0, d)} \mathbf{M} \cdot \mathbf{H} d^3 r \\ & + \mu_0 \int_{\mathbb{R}^3} \int_{\mathbb{R}^3} \frac{\nabla \cdot \mathbf{M}(\mathbf{r}) \nabla \cdot \mathbf{M}(\mathbf{r}')}{8\pi |\mathbf{r} - \mathbf{r}'|} d^3 r d^3 r' + \frac{Dd}{M_s^2} \int_{\Omega} \left( \overline{M}_{\parallel} \nabla \cdot \overline{\mathbf{M}}_{\perp} - \overline{\mathbf{M}}_{\perp} \cdot \nabla \overline{M}_{\parallel} \right) d^2 r. \end{aligned} \quad (2.1)$$

Here we wrote  $\mathbf{M} = (\mathbf{M}_{\perp}, M_{\parallel})$ , where we defined  $\mathbf{M}_{\perp} \in \mathbb{R}^2$  and  $M_{\parallel} \in \mathbb{R}$  to be the components of the magnetization vector  $\mathbf{M}$  that are perpendicular and parallel to the material easy axis (the  $z$ -axis), respectively, and introduced  $\overline{\mathbf{M}}$  which is the trace of  $\mathbf{M}$  on  $\Omega \times \{0\}$ . In (2.1),  $A$  is the exchange stiffness,  $K$  is the magnetocrystalline anisotropy constant,  $\mathbf{M}$  has been extended by zero outside the sample and  $\nabla \cdot \mathbf{M}$  is understood distributionally in  $\mathbb{R}^3$ ,  $\mu_0$  is the permeability of vacuum,  $\mathbf{H} = \mathbf{H}(x, y, z)$  is the applied magnetic field, and  $D$  is the Dzyaloshinskii-Moriya interaction constant, following the standard convention to write  $D$  in the units of energy per unit area. In writing the DMI

term in this specific form, we took into account that it arises as a contribution from the interface between the magnetic layer and a non-magnetic material and should, therefore, enter as a boundary term in the full three-dimensional theory.

In the above framework, the equilibrium magnetization configurations in the ferromagnetic sample correspond to either global or local minimizers of a non-local, non-convex energy functional in (2.1). This energy includes several terms, in order of appearance: the exchange term, which prefers constant magnetization configurations; the magnetocrystalline anisotropy, which favors out-of-plane magnetization configurations; the Zeeman, or applied field term, which prefers magnetizations aligned with the external field; the magnetostatic term, which prefers divergence-free configurations; and the surface DMI term, which favors chiral symmetry breaking. The origin of the latter is the antisymmetric exchange mediated by the spin-orbit coupling in the conduction band of a heavy metal at the ferromagnet-metal interface [13, 17, 19].

The variational problem associated with (2.1) poses a significant challenge for analysis. Therefore, in the following we introduce a simplified version of the energy in (2.1) that is suitable for ultrathin ferromagnetic films of thickness  $d \lesssim \ell_{ex} = \sqrt{2A/(\mu_0 M_s^2)}$ , where  $\ell_{ex}$  is the material exchange length. In this case a two-dimensional model is appropriate in which the stray field energy can be modeled by a local shape anisotropy term (see, e.g., [21]; for a more thorough mathematical discussion of the stray field effect in ultrathin films with perpendicular anisotropy, see [28]). Measuring the lengths in the units of  $\ell_{ex}$  and the energy in the units of  $Ad$ , we can rewrite the energy associated with the magnetization configuration  $\mathbf{M}(x, y, z) = M_s \mathbf{m}(x, y)$ , where  $\mathbf{m} : \Omega \rightarrow \mathbb{S}^2$ , as

$$E(\mathbf{m}) = \int_{\Omega} \left\{ |\nabla \mathbf{m}|^2 + (Q - 1) |\mathbf{m}_{\perp}|^2 - 2h_{\parallel} m_{\parallel} - 2\mathbf{h}_{\perp} \cdot \mathbf{m}_{\perp} + \kappa (m_{\parallel} \nabla \cdot \mathbf{m}_{\perp} - \mathbf{m}_{\perp} \cdot \nabla m_{\parallel}) \right\} d^2 r, \quad (2.2)$$

where we defined  $\mathbf{m}_{\perp} \in \mathbb{R}^2$  and  $m_{\parallel} \in \mathbb{R}$  to be the respective components of the unit magnetization vector  $\mathbf{m}$  and introduced the dimensionless quality factor  $Q$  and the dimensionless DMI strength  $\kappa$ :

$$Q = \frac{2K}{\mu_0 M_s^2}, \quad \kappa = D \sqrt{\frac{2}{\mu_0 M_s^2 A}}, \quad (2.3)$$

where  $D$  is the DMI constant [50]. In (2.2), we also introduced a dimensionless applied magnetic field  $\mathbf{h} = (\mathbf{h}_{\perp}, h_{\parallel}) = \mathbf{H}/M_s$ , with  $\mathbf{h}_{\perp} \in \mathbb{R}^2$  and  $h_{\parallel} \in \mathbb{R}$ .

We are interested in the regime in which the film favors magnetizations that are normal to the film plane, i.e., when  $Q > 1$ . Also, since the energy is invariant with respect to the transformation

$$\kappa \rightarrow -\kappa, \quad \mathbf{m}_{\perp} \rightarrow -\mathbf{m}_{\perp}, \quad \mathbf{h}_{\perp} \rightarrow -\mathbf{h}_{\perp}, \quad (2.4)$$

without loss of generality we can assume  $\kappa$  to be positive.

Figure 2: Two types of one-dimensional domain walls due to DMI: (a) interior wall; (b) edge wall. In the upper panels,  $\theta$  stands for the angle between  $\mathbf{m}$  and the  $z$ -axis. The vector  $\mathbf{m}$  rotates in the  $xz$ -plane (lower panels).

### 3 The problem in one dimension

We begin by considering an idealized situation in which the ferromagnetic film occupies either the whole plane or a half-plane, which leads to two basic types of domain walls considered below (see Fig. 2). These are the magnetization configurations that vary in one direction only. In the case of the half-plane, the magnetization is also assumed to vary in the direction normal to the film edge. Throughout this section, we set the applied magnetic field  $\mathbf{h}$  to zero.

#### 3.1 Interior wall

Consider first the whole space situation, in which case we may assume that

$$\Omega = \{(x, y) \in \mathbb{R}^2 : x \in \mathbb{R}, 0 < y < 1\}, \quad (3.1)$$

with periodic boundary conditions at  $y = 0$  and  $y = 1$ . We then take  $\mathbf{m}$  to be a one-dimensional profile, i.e.,  $\mathbf{m} = \mathbf{m}(x)$ . Then we may write the energy associated with  $\mathbf{m}$  in the form

$$E(\mathbf{m}) = \int_{-\infty}^{\infty} \left\{ |\mathbf{m}'|^2 + (Q - 1)|\mathbf{m}_{\perp}|^2 + \kappa \left( m_{\parallel}(\hat{x} \cdot \mathbf{m}_{\perp})' - (\hat{x} \cdot \mathbf{m}_{\perp})m'_{\parallel} \right) \right\} dx, \quad (3.2)$$

where primes denote the derivative with respect to the  $x$  variable and  $\hat{x}$  is the unit vector in the direction of the  $x$ -axis. We are interested in the global energy minimizers of the energy in (3.2) that obey the following conditions at infinity:

$$\lim_{x \rightarrow \pm\infty} m_{\parallel}(x) = \pm 1, \quad \lim_{x \rightarrow \pm\infty} \mathbf{m}_{\perp}(x) = 0. \quad (3.3)$$

On heuristic grounds, one expects that the optimal domain wall profile has the form of the *Dzyaloshinskii wall* [50]. Namely, one expects that in the domain wall the magnetization rotates around the direction of the  $y$ -axis. Hence, introducing an ansatz

$$\mathbf{m} = (\sin \theta, 0, \cos \theta), \quad (3.4)$$

one can rewrite the energy in (3.2) as [45]

$$E(\mathbf{m}) = \int_{-\infty}^{\infty} \left\{ |\theta'|^2 + (Q - 1) \sin^2 \theta + \kappa \theta' \right\} dx. \quad (3.5)$$

Observe, however, that a priori the energy in (3.5) is not well defined in the natural class of  $\theta \in H_{loc}^1(\mathbb{R})$ , since the last term in the energy is not sign definite and does not necessarily make sense as the Lebesgue integral on the whole real line. This fact is closely related to the chiral nature of DMI, favoring oscillations of the magnetization vector. A simple counterexample, in which the first two terms of the energy in (3.5) are well defined, while the last one is not, is given by the function  $\theta(x) = \frac{\pi}{2} - \text{Si}(x)$ , where  $\text{Si}(x) = \int_0^x t^{-1} \sin t \, dt$  is the sine integral function. It is also worth noting that if one were to define the energy in (3.5) as the limit of the energies on large finite domains, then its minimum value would be strictly greater than that obtained from the integral on the whole real line due to the presence of edge domain walls [45] (see also Sec. 3.2 for further details).

To fix the issue above, one needs to assume that  $\theta' \in L^1(\mathbb{R})$ , which introduces a bound on the total variation of  $\theta$  on  $\mathbb{R}$ . This, in turn, implies that the limit of  $\theta(x)$  as  $x \rightarrow \pm\infty$  exists, and the last term in (3.5) becomes a boundary term. Furthermore, in order for the energy to be bounded the limits of  $\theta(x)$  at infinity must be integer multiples of  $\pi$ , and without loss of generality we may assume

$$\lim_{x \rightarrow -\infty} \theta(x) = \pi n, \quad \lim_{x \rightarrow +\infty} \theta(x) = 0, \quad n \in \mathbb{Z}. \quad (3.6)$$

The energy then becomes

$$E(\mathbf{m}) = \int_{-\infty}^{\infty} \left\{ |\theta'|^2 + (Q - 1) \sin^2 \theta \right\} dx - \kappa \pi n, \quad (3.7)$$

for  $\theta \in H_{loc}^1(\mathbb{R})$  with  $\theta' \in L^1(\mathbb{R})$  and  $\theta$  obeying (3.6), with  $n \neq 0$  to exclude the trivial case.

It is easy to see that the energy in (3.7) is uniquely minimized in the above class if and only if  $n = 1$  and  $\kappa < \kappa_c$ , where

$$\kappa_c = \frac{4\sqrt{Q-1}}{\pi}. \quad (3.8)$$

In this case the optimal profile is, up to translations, given by [45]

$$\theta(x) = 2 \arctan e^{-x\sqrt{Q-1}}, \quad (3.9)$$

and the wall energy is given by

$$\sigma_{wall} = 4\sqrt{Q-1} - \pi\kappa > 0. \quad (3.10)$$

Indeed, minimizers of (3.7) with  $n = \pm 1$  among all admissible  $\theta$  are well known to exist due to the good coercivity and lower semicontinuity properties of those terms (for technical details in a related problem, see [12]). The profile in (3.9) is then the unique solution, up to translations and sign, of the Euler-Lagrange equation associated with (3.7) satisfying (3.6). At the same time, for  $|n| \geq 2$  the energy is easily seen to satisfy  $E(\theta) \geq |n|\sigma_{wall}$ . Hence, by inspection the minimizer with  $n = +1$  corresponds to the global minimizer for all  $n \neq 0$ , with the sign of  $n$  corresponding to the wall chirality imparted by DMI.

We remark that, in contrast to the above situation, the problem associated with (3.2) does not admit minimizers for  $\kappa > \kappa_c$ , since in this case the energy is not bounded below and favors helical structures [45].

The following theorem establishes existence and uniqueness of the minimizers of the one-dimensional domain wall energy in (3.2) among all profiles satisfying (3.3) *without* assuming the ansatz in (3.4). In view of the discussion above, an appropriate admissible class for the energy is given by

$$\mathcal{A} = \{\mathbf{m} \in H_{loc}^1(\mathbb{R}; \mathbb{S}^2) : \mathbf{m}' \in L^1(\mathbb{R}; \mathbb{R}^3)\}. \quad (3.11)$$

The theorem below confirms the expectation that the domain wall profile is given by (3.4) and (3.9) for all  $\kappa$  below a critical value, although the latter turns out to be slightly lower than the expected threshold value of  $\kappa = \kappa_c$  given by (3.8).

**Theorem 1.** *Let  $0 < \kappa < \sqrt{Q-1}$ . Then there exists a unique, up to translations, minimizer  $\mathbf{m} \in \mathcal{A}$  of (3.2) satisfying (3.3). The minimizer  $\mathbf{m}$  has the form in (3.4) with  $\theta$  given by (3.9), and the minimal energy is given by  $\sigma_{wall}$  from (3.10).*

*Proof.* The proof proceeds by showing directly that the profile given by (3.4) and (3.9) is the unique minimizer via establishing a sharp lower bound for the energy. Assume without loss of generality that  $E(\mathbf{m}) < +\infty$ . Then by dominated convergence theorem we have

$$E(\mathbf{m}) = \int_{-\infty}^{\infty} \left( |\mathbf{m}'|^2 + (Q-1)|\mathbf{m}_{\perp}|^2 \right) dx + \kappa \lim_{R \rightarrow \infty} \int_{-R}^R \left( m_{\parallel}(\hat{x} \cdot \mathbf{m}_{\perp})' - (\hat{x} \cdot \mathbf{m}_{\perp})m'_{\parallel} \right) dx, \quad (3.12)$$

and  $|\mathbf{m}_{\perp}(x)| \rightarrow 0$  as  $x \rightarrow \pm\infty$  [10, Corollary 8.9]. Using integration by parts [10, Corollary 8.10], the last integral may be rewritten as

$$\int_{-R}^R \left( m_{\parallel}(\hat{x} \cdot \mathbf{m}_{\perp})' - (\hat{x} \cdot \mathbf{m}_{\perp})m'_{\parallel} \right) dx = (\hat{x} \cdot \mathbf{m}_{\perp}(x))m_{\parallel}(x) \Big|_{-R}^R - 2 \int_{-R}^R (\hat{x} \cdot \mathbf{m}_{\perp}) m'_{\parallel} dx. \quad (3.13)$$

Therefore, passing to the limit we obtain that

$$E(\mathbf{m}) = \int_{-\infty}^{\infty} \left( |\mathbf{m}'|^2 + (Q-1)|\mathbf{m}_{\perp}|^2 - 2\kappa(\hat{x} \cdot \mathbf{m}_{\perp})m'_{\parallel} \right) dx. \quad (3.14)$$

We now trivially estimate the DMI term from below to obtain

$$E(\mathbf{m}) \geq \int_{-\infty}^{\infty} \left( |\mathbf{m}'|^2 + (Q-1)|\mathbf{m}_{\perp}|^2 - 2\kappa |\mathbf{m}_{\perp}| |m'_{\parallel}| \right) dx. \quad (3.15)$$

Next, we use the standard trick [29] to estimate the exchange energy by the term involving only  $|m'_{\parallel}|$ . In the following, we spell out the details of the argument, paying special attention to the optimality of the obtained estimates. We start by applying the weak chain rule [10, Proposition 9.5] to the identity  $|\mathbf{m}_{\perp}|^2 + m_{\parallel}^2 = 1$ . This yields:

$$m_{\parallel}^2 |m'_{\parallel}|^2 = |\mathbf{m}_{\perp} \cdot \mathbf{m}'_{\perp}|^2 \leq |\mathbf{m}_{\perp}|^2 |\mathbf{m}'_{\perp}|^2 \quad \text{for a.e. } x \in \mathbb{R}. \quad (3.16)$$

Therefore, for a.e.  $x \in \mathbb{R}$  such that  $|m_{\parallel}| < 1$  we can write

$$\frac{m_{\parallel}^2 |m'_{\parallel}|^2}{1 - m_{\parallel}^2} \leq |\mathbf{m}'_{\perp}|^2. \quad (3.17)$$

Thus

$$\int_{-\infty}^{\infty} |\mathbf{m}'|^2 dx = \int_{-\infty}^{\infty} \left( |\mathbf{m}'_{\perp}|^2 + |m'_{\parallel}|^2 \right) dx \geq \int_{\{|m_{\parallel}| < 1\}} \frac{|m'_{\parallel}|^2}{1 - m_{\parallel}^2} dx. \quad (3.18)$$

Writing the lower bound for the energy in terms of  $m_{\parallel}$ , with the help of (3.15) and (3.18) we obtain

$$E(\mathbf{m}) \geq \int_{\{|m_{\parallel}| < 1\}} \left( \frac{|m'_{\parallel}|^2}{1 - m_{\parallel}^2} + (Q-1)(1 - m_{\parallel}^2) \right) dx - 2\kappa \int_{-\infty}^{\infty} \sqrt{1 - m_{\parallel}^2} |m'_{\parallel}| dx. \quad (3.19)$$

This inequality may be rewritten in the following Modica-Mortola type form

$$\begin{aligned} E(\mathbf{m}) &\geq 2 \int_{-\infty}^{\infty} \left( \sqrt{Q-1} - \kappa \sqrt{1 - m_{\parallel}^2} \right) |m'_{\parallel}| dx \\ &\quad + \int_{\{|m_{\parallel}| < 1\}} \left( \frac{|m'_{\parallel}|}{\sqrt{1 - m_{\parallel}^2}} - \sqrt{(Q-1)(1 - m_{\parallel}^2)} \right)^2 dx, \end{aligned} \quad (3.20)$$

where we extended the domain of integration in the first term to the whole real line in view of the fact that by (3.16) we have  $m'_{\parallel} = 0$  whenever  $|m_{\parallel}| = 1$ .

We now turn to showing that the energy is minimized by the profile given by (3.4) with  $\theta$  given by (3.9). Indeed, from (3.20) we have for any  $R > 0$ :

$$\begin{aligned}
E(\mathbf{m}) &\geq 2 \int_{-R}^R \left( \sqrt{Q-1} - \kappa \sqrt{1-m_{\parallel}^2} \right) |m'_{\parallel}| dx \\
&\geq 2 \int_{-R}^R \left( \sqrt{Q-1} - \kappa \sqrt{1-m_{\parallel}^2} \right) m'_{\parallel} dx \\
&= \left\{ 2m_{\parallel}(x) \sqrt{Q-1} - \kappa \left( m_{\parallel}(x) \sqrt{1-m_{\parallel}^2(x)} + \arcsin(m_{\parallel}(x)) \right) \right\} \Big|_{-R}^R, \quad (3.21)
\end{aligned}$$

where we used the assumption that  $\kappa < \sqrt{Q-1}$  to go from the first to the second line. Finally, passing to the limit as  $R \rightarrow \infty$  and using (3.3), we obtain

$$E(\mathbf{m}) \geq \sigma_{wall}, \quad (3.22)$$

where  $\sigma_{wall}$  is defined in (3.10). At the same time, by the computation at the beginning of this section the inequality above is an equality when  $\mathbf{m}$  is given by (3.4) with  $\theta$  from (3.9).

It remains to prove that the profile given by (3.4) with  $\theta$  from (3.9) is the unique, up to translations, minimizer of the energy that satisfies (3.3). Without loss of generality, we may assume that  $m_{\parallel}(0) = 0$ , in view of the continuity of  $m_{\parallel}(x)$  and (3.3). Since the minimal value of the energy is attained by dropping the last term in (3.20) and replacing  $|m'_{\parallel}|$  with  $m'_{\parallel}$ , we have  $m'_{\parallel}(x) \geq 0$  for a.e.  $x \in \mathbb{R}$ , and  $m_{\parallel}$  satisfies

$$m'_{\parallel} = \sqrt{Q-1}(1-m_{\parallel}^2) \quad \text{for a.e. } x \in I, \quad (3.23)$$

where  $I = (a, b)$  with  $-\infty \leq a < 0 < b \leq \infty$ . Since the right-hand side of (3.23) is continuous,  $m_{\parallel}$  is the unique classical solution of (3.23) that satisfies  $m_{\parallel}(0) = 0$ , which is explicitly  $m_{\parallel}(x) = \tanh(x\sqrt{Q-1})$ . Lastly, the inequality in (3.16) becomes equality when  $\mathbf{m}'_{\perp}$  is parallel to  $\mathbf{m}_{\perp}$  and, hence,  $\mathbf{m}_{\perp} = g\mathbf{b}$  for some constant vector  $\mathbf{b} \in \mathbb{R}^2$  and a scalar function  $g : \mathbb{R} \rightarrow [-1, 1]$ . In turn, to make an inequality in (3.15) an equality, one needs to choose  $\mathbf{b} = \hat{x}$  and  $g \geq 0$ . In view of the unit length constraint for  $|\mathbf{m}|$ , this translates into  $\mathbf{m}_{\perp} = \hat{x} \operatorname{sech}^2(x\sqrt{Q-1})$ . The obtained profile  $\mathbf{m} = (\mathbf{m}_{\perp}, m_{\parallel})$  is then precisely the one given by (3.4) with  $\theta$  from (3.9).  $\square$

We note that the arguments in the proof of Theorem 1 do not carry over to the range  $\sqrt{Q-1} < \kappa \leq \kappa_c$ , since in this range we can no longer reduce the energy by passing to the configurations in the form given by (3.4). Nevertheless, an inspection of the proof shows that the statement of Theorem 1 remains true for all  $\mathbf{m} = (\mathbf{m}_{\perp}, m_{\parallel})$  such that  $m_{\parallel}(x)$  is a non-decreasing function of  $x$ . Hence, we have the following result.

**Theorem 2.** *For any  $\kappa > 0$ , there exists a unique, up to translations, minimizer of (3.2) among all  $\mathbf{m} = (\mathbf{m}_{\perp}, m_{\parallel}) \in \mathcal{A}$  satisfying (3.3) and  $m'_{\parallel} \geq 0$ . The minimizer  $\mathbf{m}$  has the form in (3.4) with  $\theta$  given by (3.9), and the minimal energy is given by  $\sigma_{wall}$  from (3.10).*

**Remark 3.** We point out that due to the presence of the edge domain walls (see the following subsection) the minimizers of the energy in (2.2) in the form of a Dzyaloshinskii wall on a strip  $\Omega = \mathbb{R} \times (0, L)$  are not one-dimensional for any  $L > 0$ . Nevertheless, if one assumes periodic boundary conditions instead of the natural boundary conditions at the edges of the strip, an examination of the proof of Theorem 1 shows that the global minimizer is still given by (3.4) and (3.9) in this case.

## 3.2 Edge wall

Consider now the half-plane situation, in which case we may assume that

$$\Omega = \{(x, y) \in \mathbb{R}^2 : x > 0, 0 < y < 1\}, \quad (3.24)$$

with periodic boundary conditions at  $y = 0$  and  $y = 1$ . Taking  $\mathbf{m}$  to be a one-dimensional profile, i.e.,  $\mathbf{m} = \mathbf{m}(x)$ , we write

$$E(\mathbf{m}) = \int_0^\infty \left\{ |\mathbf{m}'|^2 + (Q - 1)|\mathbf{m}_\perp|^2 + \kappa \left( m_\parallel (\hat{x} \cdot \mathbf{m}_\perp)' - (\hat{x} \cdot \mathbf{m}_\perp) m'_\parallel \right) \right\} dx, \quad (3.25)$$

where, as before,  $\hat{x}$  is the unit vector in the direction of the  $x$ -axis. Once again, in order for this energy to be bounded, we must have  $|\mathbf{m}_\perp(x)| \rightarrow 0$  as  $x \rightarrow \infty$ . Hence, in view of the symmetry

$$\mathbf{m}_\perp \rightarrow -\mathbf{m}_\perp, \quad m_\parallel \rightarrow -m_\parallel, \quad (3.26)$$

without loss of generality we may assume that

$$\lim_{x \rightarrow \infty} m_\parallel(x) = 1. \quad (3.27)$$

Note, however, that the value of  $\mathbf{m}(0)$  is not fixed and needs to be determined for the optimal domain wall profile at the material edge. Such edge domains walls were first discussed in [45].

Since for  $\kappa > \kappa_c$ , where  $\kappa_c$  is given by (3.8), the energy favors helical structures [45] and, hence, is not bounded below on the semi-infinite interval as well as on the whole line, throughout the rest of this section we assume that  $\kappa < \kappa_c$ . Assuming also the ansatz from (3.4) and arguing as in the previous subsection, for  $\theta \in H^1(\mathbb{R}^+)$  with  $\theta' \in L^1(\mathbb{R}^+)$  we may write the energy in (3.25) as

$$E(\mathbf{m}) = \int_0^\infty \left\{ |\theta'|^2 + (Q - 1) \sin^2 \theta \right\} dx - \kappa \theta(0), \quad (3.28)$$

which is easily seen to be minimized at fixed  $\theta(0) = \theta_0 \in (0, \pi)$  by

$$\theta(x) = 2 \arctan e^{(x_0 - x)\sqrt{Q-1}}, \quad x_0 = \frac{\ln \tan\left(\frac{\theta_0}{2}\right)}{\sqrt{Q-1}}. \quad (3.29)$$

Indeed, using the Modica-Mortola trick [37], we rewrite the energy in (3.28) as

$$\begin{aligned} E(\mathbf{m}) &= 2\sqrt{Q-1} \int_0^\infty |\sin \theta| |\theta'| dx + \int_0^\infty \left( |\theta'| - \sqrt{Q-1} |\sin \theta| \right)^2 dx - \kappa \theta_0 \\ &\geq - \int_0^\infty \left( 2\sqrt{Q-1} |\sin \theta| - \kappa \right) \theta' dx = \int_0^{\theta_0} \left( 2\sqrt{Q-1} |\sin \theta| - \kappa \right) d\theta. \end{aligned} \quad (3.30)$$

In particular, the inequality above becomes an equality when  $\theta$  is given by (3.29).

We now show that there exists a unique value of  $\theta_0 = \theta_0^* \in (0, \pi)$  for which the function from (3.29) yields the absolute minimum of the energy in (3.28) for  $\kappa < \kappa_c$ . Denoting the right-hand side in (3.30) by  $F(\theta_0)$ , we observe that  $F(0) = 0$ ,  $F'(0) < 0$ , and  $F(\theta_0) = F(\theta_0 - \pi) + \sigma_{wall}$ , where  $\sigma_{wall} > 0$  is given by (3.10), for all  $\theta_0 \geq \pi$ . Therefore, for  $\theta_0 \geq 0$  it is enough to consider the values of  $\theta_0 \in (0, \pi)$ , for which we have explicitly

$$F(\theta_0) = 2\sqrt{Q-1} (1 - \cos \theta_0) - \kappa \theta_0. \quad (3.31)$$

A simple computation then shows that for  $\theta_0 \geq 0$  the function  $F(\theta_0)$  is uniquely minimized by

$$\theta_0^* = \arcsin \left( \frac{\kappa}{2\sqrt{Q-1}} \right), \quad (3.32)$$

and the minimal value of  $F(\theta_0)$  is given by

$$\sigma_{edge} = 2\sqrt{Q-1} \left( 1 - \sqrt{1 - \frac{\kappa^2}{4(Q-1)}} \right) - \kappa \arcsin \left( \frac{\kappa}{2\sqrt{Q-1}} \right) < 0. \quad (3.33)$$

In fact, this is also an absolute lower bound for  $E(\mathbf{m})$  in (3.28), since for  $\theta_0 < 0$  the energy remains positive. Furthermore, since  $\theta_0^* \in (0, \pi)$ , this minimum value is attained by the profile in (3.29) with  $\theta_0 = \theta_0^*$ . Interestingly, we find that  $\theta_0^* \in (0, \arcsin \frac{2}{\pi})$ , spanning the range from  $0^\circ$  at  $\kappa = 0$  to about  $39.5^\circ$  for  $\kappa = \kappa_c$ . Thus, the global minimizer of the energy in (3.25) among all profiles satisfying (3.4) has the form of an edge domain wall whose profile is given by (3.29), up to a sign, with an optimal value of  $\theta$  at the edge.

We now prove, once again, that this picture remains true without the ansatz in (3.4) for a slightly smaller range of the values of  $\kappa < \kappa_c$ . The appropriate admissible class for the energy in (3.25) is now

$$\mathcal{A}^+ = \{ \mathbf{m} \in H_{loc}^1(\mathbb{R}^+; \mathbb{S}^2) : \mathbf{m}' \in L^1(\mathbb{R}^+; \mathbb{R}^3) \}. \quad (3.34)$$

**Theorem 4.** *Let  $0 < \kappa < \sqrt{Q-1}$ . Then there exists a unique minimizer  $\mathbf{m} \in \mathcal{A}^+$  of (3.25) satisfying (3.27). The minimizer  $\mathbf{m}$  has the form in (3.4) with  $\theta$  given by (3.29) and  $\theta_0 = \theta_0^*$  from (3.32), and the minimal energy is given by  $\sigma_{edge}$  from (3.33).*

*Proof.* The proof proceeds exactly as in the case of Theorem 1, except that there is now an extra contribution from the boundary of the domain at  $x = 0$ . Namely, instead of (3.14) we obtain

$$E(\mathbf{m}) = \int_0^\infty \left( |\mathbf{m}'|^2 + (Q-1)|\mathbf{m}_\perp|^2 - 2\kappa(\hat{x} \cdot \mathbf{m}_\perp)m'_\parallel \right) dx - \kappa m_\parallel(0)(\hat{x} \cdot \mathbf{m}_\perp(0)). \quad (3.35)$$

Estimating both terms coming from DMI from below as

$$E(\mathbf{m}) \geq \int_0^\infty \left( |\mathbf{m}'|^2 + (Q-1)|\mathbf{m}_\perp|^2 - 2\kappa |\mathbf{m}_\perp| |m'_\parallel| \right) dx - \kappa |m_\parallel(0)| |\mathbf{m}_\perp(0)|, \quad (3.36)$$

and retracing the steps in the proof of Theorem 1, we obtain

$$\begin{aligned} E(\mathbf{m}) &\geq 2 \int_0^\infty \left( \sqrt{Q-1} - \kappa \sqrt{1-m_\parallel^2} \right) |m'_\parallel| dx - \kappa |m_\parallel(0)| \sqrt{1-m_\parallel^2(0)} \\ &\quad + \int_{\{|m_\parallel| < 1\}} \left( \frac{|m'_\parallel|}{\sqrt{1-m_\parallel^2}} - \sqrt{(Q-1)(1-m_\parallel^2)} \right)^2 dx. \end{aligned} \quad (3.37)$$

With the help of the identity  $|m'_\parallel| = |m_\parallel|'$  [32, Theorem 6.17] and our assumption on  $\kappa$ , we can further estimate the right-hand side in (3.37) from below as

$$\begin{aligned} E(\mathbf{m}) &\geq 2 \int_0^R \left( \sqrt{Q-1} - \kappa \sqrt{1-m_\parallel^2} \right) |m'_\parallel| dx - \kappa |m_\parallel(0)| \sqrt{1-m_\parallel^2(0)} \\ &\geq 2 \int_0^R \left( \sqrt{Q-1} - \kappa \sqrt{1-m_\parallel^2} \right) |m_\parallel|' dx - \kappa |m_\parallel(0)| \sqrt{1-m_\parallel^2(0)} \\ &= \left\{ 2|m_\parallel(x)| \sqrt{Q-1} - \kappa \left( |m_\parallel(x)| \sqrt{1-m_\parallel^2(x)} + \arcsin(|m_\parallel(x)|) \right) \right\} \Big|_0^R \\ &\quad - \kappa |m_\parallel(0)| \sqrt{1-m_\parallel^2(0)}. \end{aligned} \quad (3.38)$$

Simplifying the expression above and passing to the limit, we arrive at

$$E(\mathbf{m}) \geq 2\sqrt{Q-1}(1 - |m_\parallel(0)|) - \kappa \arccos |m_\parallel(0)|. \quad (3.39)$$

However, the right-hand side of (3.39) is nothing but  $F(\arccos |m_\parallel(0)|)$ , where  $F$  is given by (3.31). Thus,  $E(\mathbf{m}) \geq \sigma_{edge}$ , and equality holds for the profile given by (3.4) and (3.29). Furthermore, as in the case of Theorem 1, the inequality above is strict for any other wall profile. This concludes the proof.  $\square$

**Remark 5.** According to Theorem 4, the magnetization vector in the edge wall that asymptotes to  $m_\parallel = +1$  in the sample interior acquires a component that points along the inner normal at the sample edge. At the same time, by (3.26) the magnetization vector in the edge wall that asymptotes to  $m_\parallel = -1$  in the sample interior acquires a component that points along the outer normal at the sample edge.

Figure 3: Schematics of a magnetization configuration containing edge walls and a Dzyaloshinskii wall. The arrows show the in-plane components of the magnetization vector, the colors correspond to the out-of-plane component (“red” is up, “violet” is down, also indicated by up/down symbols).

## 4 The problem in two dimensions

We now go back to the original two-dimensional problem and consider the regime in which the Dzyaloshinskii domain walls are present (for an illustration, see Fig. 3). The appearance of these domain walls requires that the lateral extent of the ferromagnetic sample be sufficiently large. Therefore, we introduce the domain  $\Omega_\varepsilon = \varepsilon^{-1}\Omega$ , where  $\varepsilon \ll 1$ , and redefine the energy in (2.2) on  $\Omega_\varepsilon$ :

$$E(\mathbf{m}) = \int_{\Omega_\varepsilon} \left\{ |\nabla \mathbf{m}|^2 + (Q - 1)|\mathbf{m}_\perp|^2 - 2\mathbf{h}_\varepsilon \cdot \mathbf{m} + \kappa (m_\parallel \nabla \cdot \mathbf{m}_\perp - \mathbf{m}_\perp \cdot \nabla m_\parallel) \right\} d^2r, \quad (4.1)$$

where we also defined a rescaled applied field  $\mathbf{h}_\varepsilon = (\mathbf{h}_\perp^\varepsilon, h_\parallel^\varepsilon) = \varepsilon(\mathbf{h}_\perp^0, h_\parallel^0) = \varepsilon\mathbf{h}_0$ , chosen to have an appropriate balance between the Zeeman and the domain wall energies (see below). We then rescale the domain back to  $\Omega$  and the energy by a factor of  $\varepsilon$ , which leads to the following family of energies:

$$E_\varepsilon(\mathbf{m}) = \int_{\Omega} \left\{ \varepsilon |\nabla \mathbf{m}|^2 + \varepsilon^{-1}(Q - 1)|\mathbf{m}_\perp|^2 - 2h_\parallel^0 m_\parallel - 2\mathbf{h}_\perp^0 \cdot \mathbf{m}_\perp + \kappa (m_\parallel \nabla \cdot \mathbf{m}_\perp - \mathbf{m}_\perp \cdot \nabla m_\parallel) \right\} d^2r. \quad (4.2)$$

The purpose of this section is to understand the behavior of global energy minimizers of  $E_\varepsilon$  as  $\varepsilon \rightarrow 0$ , which corresponds to the regime of interest. Throughout the rest of this

paper,  $\Omega \subset \mathbb{R}^2$  is assumed to be a bounded domain with boundary of class  $C^2$ . This is done merely to reduce the technicalities of the proofs and focus on the vectorial aspects of the problem involving DMI. With slight modifications, the proof should apply to the case when  $\partial\Omega$  is a union of finitely many curve segments of class  $C^1$  (see also [38, Remark 1.3]).

Our main tool for the analysis of the variational problem associated with (4.2) will be the following  $\Gamma$ -convergence result.

**Theorem 6.** *Let  $\mathbf{h}_0 = (\mathbf{h}_\perp^0, h_\parallel^0) \in L^\infty(\Omega; \mathbb{R}^3)$ ,  $Q > 1$  and  $0 < \kappa < \sqrt{Q-1}$ . Then, as  $\varepsilon \rightarrow 0$ , we have  $E_\varepsilon \xrightarrow{\Gamma} E_0$  with respect to the  $L^1$  convergence, where*

$$E_0(m_\parallel) = \sigma_{edge} \mathcal{H}^1(\partial\Omega) + \sigma_{wall} \mathcal{H}^1(\partial^* \Omega^+) - 2 \int_\Omega h_\parallel^0 m_\parallel d^2r, \quad (4.3)$$

in which  $m_\parallel \in BV(\Omega; \{-1, 1\})$  and  $\partial^* \Omega^+$  is the reduced boundary of the set  $\Omega^+$ , where

$$\Omega^\pm = \{x \in \Omega : m_\parallel(x) = \pm 1\}. \quad (4.4)$$

More precisely:

i) For any sequence of  $\mathbf{m}_\varepsilon = (\mathbf{m}_\perp^\varepsilon, m_\parallel^\varepsilon) \in H^1(\Omega; \mathbb{S}^2)$  such that  $\limsup_{\varepsilon \rightarrow 0} E_\varepsilon(\mathbf{m}_\varepsilon) < +\infty$  there is a subsequence (not relabeled) and a function  $m_\parallel^0 \in BV(\Omega; \{-1, 1\})$  such that  $m_\parallel^\varepsilon \rightarrow m_\parallel^0$  and  $|\mathbf{m}_\perp^\varepsilon| \rightarrow 0$  in  $L^1(\Omega)$  as  $\varepsilon \rightarrow 0$ , and

$$\liminf_{\varepsilon \rightarrow 0} E_\varepsilon(\mathbf{m}_\varepsilon) \geq E_0(m_\parallel^0). \quad (4.5)$$

ii) For any  $m_\parallel^0 \in BV(\Omega; \{-1, 1\})$  there is a sequence of  $\mathbf{m}_\varepsilon = (\mathbf{m}_\perp^\varepsilon, m_\parallel^\varepsilon) \in H^1(\Omega; \mathbb{S}^2)$  such that  $m_\parallel^\varepsilon \rightarrow m_\parallel^0$  and  $|\mathbf{m}_\perp^\varepsilon| \rightarrow 0$  in  $L^1(\Omega)$  as  $\varepsilon \rightarrow 0$ , and

$$\limsup_{\varepsilon \rightarrow 0} E_\varepsilon(\mathbf{m}_\varepsilon) \leq E_0(m_\parallel^0). \quad (4.6)$$

*Proof.* The proof follows the classical argument of Modica [38] adapted to the vectorial micromagnetic setting and taking into account the boundary contributions to the energy. The latter arise after integration by parts:

$$\begin{aligned} E_\varepsilon(\mathbf{m}) = \int_\Omega \left( \varepsilon |\nabla \mathbf{m}|^2 + \varepsilon^{-1}(Q-1)|\mathbf{m}_\perp|^2 - 2h_\parallel^0 m_\parallel - 2\mathbf{h}_\perp^0 \cdot \mathbf{m}_\perp - 2\kappa \mathbf{m}_\perp \cdot \nabla m_\parallel \right) d^2r \\ + \kappa \int_{\partial\Omega} \tilde{m}_\parallel (\tilde{\mathbf{m}}_\perp \cdot \nu) d\mathcal{H}^1(r), \end{aligned} \quad (4.7)$$

where  $\nu$  is the outward unit normal to  $\partial\Omega$  and  $(\tilde{\mathbf{m}}_\perp, \tilde{m}_\parallel)$  is the trace of  $(\mathbf{m}_\perp, m_\parallel)$  on  $\partial\Omega$ . The proof proceeds in three steps.

*Step 1: Compactness.* Given an admissible sequence of  $\mathbf{m}_\varepsilon = (\mathbf{m}_\perp^\varepsilon, m_\parallel^\varepsilon)$  satisfying  $E_\varepsilon(\mathbf{m}_\varepsilon) \leq C$  as  $\varepsilon \rightarrow 0$  for some  $C > 0$  independent of  $\varepsilon$ , with the help of (4.7) and an elementary bound on the DMI term we can write

$$\begin{aligned} \int_{\Omega} \left( \varepsilon |\nabla \mathbf{m}_\varepsilon|^2 + \varepsilon^{-1} (Q - 1) |\mathbf{m}_\perp^\varepsilon|^2 - 2\kappa |\mathbf{m}_\perp^\varepsilon| |\nabla m_\parallel^\varepsilon| \right) d^2r \\ \leq C + 2\|\mathbf{h}_0\|_{L^\infty(\Omega)} |\Omega| + \kappa \mathcal{H}^1(\partial\Omega). \end{aligned} \quad (4.8)$$

Therefore, from (3.17) we obtain

$$\begin{aligned} \int_{\Omega \cap \{|m_\parallel^\varepsilon| < 1\}} \left( \frac{\varepsilon |\nabla m_\parallel^\varepsilon|^2}{1 - |m_\parallel^\varepsilon|^2} + \varepsilon^{-1} (Q - 1) (1 - |m_\parallel^\varepsilon|^2) \right) d^2r \\ - 2\kappa \int_{\Omega} \sqrt{1 - |m_\parallel^\varepsilon|^2} |\nabla m_\parallel^\varepsilon| d^2r \leq C', \end{aligned} \quad (4.9)$$

for some constant  $C' > 0$  independent of  $\varepsilon$ . Applying the Modica-Mortola trick to the first line in (4.9) and using the fact that by (3.16) we have  $|\nabla m_\parallel^\varepsilon| = 0$  whenever  $|m_\parallel^\varepsilon| = 1$ , we obtain

$$2 \int_{\Omega} \left( \sqrt{Q - 1} - \kappa \sqrt{1 - |m_\parallel^\varepsilon|^2} \right) |\nabla m_\parallel^\varepsilon| d^2r \leq C'. \quad (4.10)$$

This is equivalent to  $\int_{\Omega} |\nabla \Phi(m_\parallel^\varepsilon)| d^2r \leq C'$ , where

$$\Phi(s) = 2 \int_0^s \left( \sqrt{Q - 1} - \kappa \sqrt{1 - t^2} \right) dt = 2s\sqrt{Q - 1} - \kappa s\sqrt{1 - s^2} - \kappa \arcsin s \quad (4.11)$$

is a continuously differentiable, strictly increasing odd function of  $s \in [-1, 1]$ . Furthermore, by our assumption on  $\kappa$  we have  $0 < 2(\sqrt{Q - 1} - \kappa) \leq \Phi'(s) \leq 2\sqrt{Q - 1}$ . Therefore, by weak chain rule [10, Proposition 9.5] we have

$$\|m_\parallel^\varepsilon\|_{W^{1,1}(\Omega)} \leq C'', \quad (4.12)$$

for some  $C'' > 0$  independent of  $\varepsilon$ . In turn, by compactness in  $BV(\Omega)$  and the compact embedding of  $BV(\Omega)$  into  $L^1(\Omega)$  [2], this yields, upon extraction of a subsequence, that  $m_\parallel^\varepsilon \rightarrow m_\parallel^0$  in  $L^1(\Omega)$  for some  $m_\parallel^0 \in BV(\Omega)$ .

To prove that  $|m_\parallel^0| = 1$  and, as a consequence, that  $|\mathbf{m}_\perp^\varepsilon| \rightarrow 0$  in  $L^1(\Omega)$ , we combine (4.9) and (4.12) to get

$$\varepsilon^{-1} (Q - 1) \int_{\Omega} \left( 1 - |m_\parallel^\varepsilon|^2 \right) d^2r \leq C' + 2\kappa C''. \quad (4.13)$$

Therefore, the integral in the left-hand side of (4.13) converges to zero as  $\varepsilon \rightarrow 0$  and, hence,  $m_\parallel^\varepsilon(x) \rightarrow \pm 1$  for a.e.  $x \in \Omega$ . This concludes the proof of the compactness part of our  $\Gamma$ -convergence result.

*Step 2: Lower bound.* We now proceed to establish (4.5). By the Modica-Mortola type arguments in Step 1, we can estimate the energy from below as

$$E_\varepsilon(\mathbf{m}_\varepsilon) \geq \int_{\Omega} \left( |\nabla \Phi(m_\parallel^\varepsilon)| - 2h_\parallel^0 m_\parallel^\varepsilon - 2\mathbf{h}_\perp^0 \cdot \mathbf{m}_\perp^\varepsilon \right) d^2r - \kappa \int_{\partial\Omega} |\tilde{m}_\parallel^\varepsilon| \sqrt{1 - |\tilde{m}_\parallel^\varepsilon|^2} d\mathcal{H}^1(r). \quad (4.14)$$

Let  $u_\varepsilon = \Phi(m_\parallel^\varepsilon)$ . Then the lower bound in (4.14) may be rewritten as

$$E_\varepsilon(\mathbf{m}_\varepsilon) \geq \int_{\Omega} \left( |\nabla u_\varepsilon| - 2h_\parallel^0 m_\parallel^\varepsilon - 2\mathbf{h}_\perp^0 \cdot \mathbf{m}_\perp^\varepsilon \right) d^2r + \int_{\partial\Omega} \sigma(\tilde{u}_\varepsilon) d\mathcal{H}^1(r), \quad (4.15)$$

where  $\sigma(u) = -\kappa|\Phi^{-1}(u)|\sqrt{1 - |\Phi^{-1}(u)|^2}$  and  $\tilde{u}_\varepsilon$  is the trace of  $u_\varepsilon$  on  $\partial\Omega$ , noting that  $u = \Phi(s)$  defines a continuously differentiable one-to-one map from  $[-1, 1]$  to  $I = [-2\sqrt{Q-1} + \frac{1}{2}\pi\kappa, 2\sqrt{Q-1} - \frac{1}{2}\pi\kappa]$ . We next define

$$\tilde{\sigma}(u) = |u| + \min_{t \in I} (\sigma(t) - |t|) \quad u \in I. \quad (4.16)$$

A straightforward calculation shows that we have explicitly

$$\tilde{\sigma}(u) = |u| - \sqrt{4(Q-1) - \kappa^2} + \kappa \arcsin \sqrt{1 - \frac{\kappa^2}{4(Q-1)}}. \quad (4.17)$$

In particular,  $\tilde{\sigma}(u)$  is a 1-Lipschitz function of  $u$ , and by definition  $\tilde{\sigma}(u) \leq \sigma(u)$ . Therefore, by [38, Proposition 1.2] and the fact that  $|\mathbf{m}_\perp^\varepsilon| \rightarrow 0$  in  $L^1(\Omega)$ , proved in Step 1, we have

$$\begin{aligned} \liminf_{\varepsilon \rightarrow 0} E_\varepsilon(\mathbf{m}_\varepsilon) &\geq \liminf_{\varepsilon \rightarrow 0} \left( \int_{\Omega} |\nabla u_\varepsilon| d^2r + \int_{\partial\Omega} \tilde{\sigma}(\tilde{u}_\varepsilon) d\mathcal{H}^1(r) \right) - 2 \int_{\Omega} h_\parallel^0 m_\parallel^0 d^2r \\ &\geq \int_{\Omega} |\nabla u_0| d^2r + \int_{\partial\Omega} \tilde{\sigma}(\tilde{u}_0) d\mathcal{H}^1(r) - 2 \int_{\Omega} h_\parallel^0 m_\parallel^0 d^2r, \end{aligned} \quad (4.18)$$

where  $u_0 \in BV(\Omega; \{-2\sqrt{Q-1} + \frac{1}{2}\pi\kappa, 2\sqrt{Q-1} - \frac{1}{2}\pi\kappa\})$  and  $u_\varepsilon \rightarrow u_0$  in  $L^1(\Omega)$ . In (4.18), the first integral in the last line denotes the total variation of  $u_0$ , and the second term is understood as an integral of the trace of a BV function [2]. Notice that by (4.17) we have  $\tilde{\sigma}(\tilde{u}_0) = \sigma_{edge}$  and  $|\nabla u_0| = \frac{1}{2}\sigma_{wall}|\nabla m_\parallel^0|$ , after straightforward algebra. Therefore, the last inequality is equivalent to

$$\liminf_{\varepsilon \rightarrow 0} E_\varepsilon(\mathbf{m}_\varepsilon) \geq \frac{\sigma_{wall}}{2} \int_{\Omega} |\nabla m_\parallel^0| d^2r + \sigma_{edge} \mathcal{H}^1(\partial\Omega) - 2 \int_{\Omega} h_\parallel^0 m_\parallel^0 d^2r, \quad (4.19)$$

which coincides with (4.5) [2].

*Step 3: Upper bound.* Without loss of generality, we may assume  $h_\parallel = 0$  and  $\mathbf{h}_\perp = 0$ . Since we have to preserve the constraint  $|\mathbf{m}| = 1$ , we will construct an upper bound, using the

angle variables  $\theta$  and  $\phi$ . Namely, we define  $\mathbf{m} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$  and rewrite the energy in (4.2) in terms of  $\theta$  and  $\phi$  (assumed to be sufficiently smooth) as follows:

$$\begin{aligned} E(\mathbf{m}) = & \int_{\Omega} \left( \varepsilon |\nabla \theta|^2 + \varepsilon \sin^2 \theta |\nabla \phi|^2 + \varepsilon^{-1} (Q - 1) \sin^2 \theta \right) d^2 r \\ & + \kappa \int_{\Omega} (\sin \theta \cos \theta - \theta) \nabla \cdot \mathbf{v}(\phi) d^2 r + \kappa \int_{\partial \Omega} \theta \mathbf{v}(\phi) \cdot \nu d\mathcal{H}^1(r), \end{aligned} \quad (4.20)$$

where  $\mathbf{v}(\phi) = (\cos \phi, \sin \phi)$ , and we used integration by parts.

Let  $\Omega^{\pm}$  be defined as in (4.4) with  $m_{\parallel} = m_{\parallel}^0$ . Without loss of generality, we assume that  $\partial^* \Omega^+$  has  $C^2$  regularity, and that  $\partial^* \Omega^+$  intersects  $\partial \Omega$  transversally, if at all. We define

$$\theta_*(x) = \begin{cases} 0 & x \in \Omega^+ \\ \pi & x \in \Omega^- \end{cases}, \quad \theta_b(x) = \begin{cases} \theta_0^* & x \in \partial \Omega \setminus \partial \Omega^- \\ \pi - \theta_0^* & x \in \partial \Omega \setminus \partial \Omega^+ \end{cases}, \quad (4.21)$$

where  $\theta_0^*$  is defined in (3.32), and take a sequence of  $\theta_{\varepsilon} \in C^1(\overline{\Omega})$  such that

$$0 \leq \theta_{\varepsilon} \leq \pi, \quad \theta_{\varepsilon} \rightarrow \theta_* \text{ in } L^1(\Omega), \quad \theta_{\varepsilon} \rightarrow \theta_b \text{ in } L^1(\partial \Omega). \quad (4.22)$$

Notice that we also have  $\theta_{\varepsilon} \rightarrow \theta_*$  in  $L^q(\Omega)$  for every  $q > 1$ .

Now, for a fixed  $1 < p < 2$  we take two functions  $\phi_*^{\pm} \in W^{1,p}(\Omega^{\pm})$  with values in  $[0, 2\pi)$  such that

$$\mathbf{v}(\tilde{\phi}_*^{\pm}(x)) = \mp \nu_{\Omega^{\pm}}(x) \quad \text{for a.e. } x \in \partial \Omega^{\pm}, \quad (4.23)$$

where  $\nu_{\Omega^{\pm}}$  is the outward normal to  $\Omega^{\pm}$  and  $\tilde{\phi}_*^{\pm}$  are the traces of  $\phi_*^{\pm}$  on  $\partial \Omega^{\pm}$ , respectively. Such functions exist, for example, by [34, Theorem 2], since  $\tilde{\phi}_*^{\pm}$  are  $C^1$  functions of the arclength, except at a finite number of isolated points where they have jump discontinuities, and, hence, belong to the appropriate Besov spaces in the assumptions of [34]. Next, we define  $\phi_* \in W^{1,p}(\Omega)$  as

$$\phi_*(x) = \begin{cases} \phi_*^-(x) & x \in \Omega^- \\ \phi_*^+(x) & x \in \Omega^+ \end{cases}, \quad (4.24)$$

and observe that by construction we have

$$\mathbf{v}(\tilde{\phi}_*) = \begin{cases} \nu_{\Omega} & \text{on } \partial \Omega^- \cap \partial \Omega \\ -\nu_{\Omega} & \text{on } \partial \Omega^+ \cap \partial \Omega, \\ \nu_* & \text{on } \partial^* \Omega^+ \end{cases} \quad (4.25)$$

where  $\nu$ 's are the corresponding outward normals to the respective boundaries and  $\tilde{\phi}_*$  is the trace of  $\phi_*$  on those boundaries. We can then construct, using a regularization and a diagonal argument, a sequence of  $\phi_{\varepsilon} \in C^1(\overline{\Omega})$  such that

$$\phi_{\varepsilon} \rightarrow \phi_* \text{ in } W^{1,p}(\Omega) \quad \text{and} \quad \varepsilon |\nabla \phi_{\varepsilon}|^2 \rightarrow 0 \text{ in } L^1(\Omega). \quad (4.26)$$

It is then clear that, as  $\varepsilon \rightarrow 0$ , we have

$$\int_{\Omega} \theta_{\varepsilon} \nabla \cdot \mathbf{v}(\phi_{\varepsilon}) d^2r \rightarrow \pi \int_{\Omega^-} \nabla \cdot \mathbf{v}(\phi_*) d^2r = \pi \mathcal{H}^1(\partial^* \Omega^+) + \pi \mathcal{H}^1(\partial \Omega^- \cap \partial \Omega), \quad (4.27)$$

$$\int_{\Omega} \sin \theta_{\varepsilon} \cos \theta_{\varepsilon} \nabla \cdot \mathbf{v}(\phi_{\varepsilon}) d^2r \rightarrow 0, \quad (4.28)$$

$$\int_{\partial \Omega} \theta_{\varepsilon} \mathbf{v}(\phi_{\varepsilon}) \cdot \nu d\mathcal{H}^1(r) \rightarrow -\theta_0^* \mathcal{H}^1(\partial \Omega^+ \cap \partial \Omega) + (\pi - \theta_0^*) \mathcal{H}^1(\partial \Omega^- \cap \partial \Omega). \quad (4.29)$$

Passing to the limit as  $\varepsilon \rightarrow 0$  in the energy (4.20) and combining the terms, we obtain

$$\begin{aligned} \limsup_{\varepsilon \rightarrow 0} E(\mathbf{m}_{\varepsilon}) &= \limsup_{\varepsilon \rightarrow 0} \int_{\Omega} \left( \varepsilon |\nabla \theta_{\varepsilon}|^2 + \varepsilon^{-1} (Q - 1) \sin^2 \theta_{\varepsilon} \right) d^2r \\ &\quad - \pi \kappa \mathcal{H}^1(\partial^* \Omega^+) - \kappa \theta_0^* \mathcal{H}^1(\partial \Omega). \end{aligned} \quad (4.30)$$

In order to conclude, we need to construct a sequence of  $\theta_{\varepsilon} \in C^1(\overline{\Omega})$  satisfying (4.22) such that

$$\begin{aligned} \limsup_{\varepsilon \rightarrow 0} \int_{\Omega} \left( \varepsilon |\nabla \theta_{\varepsilon}|^2 + \varepsilon^{-1} (Q - 1) \sin^2 \theta_{\varepsilon} \right) d^2r \\ = E_0(m_{\parallel}) + \pi \kappa \mathcal{H}^1(\partial^* \Omega^+) + \kappa \theta_0^* \mathcal{H}^1(\partial \Omega). \end{aligned} \quad (4.31)$$

This construction was done in a more general setting in [42, Lemma 2]) and, therefore, using this result we conclude that  $\limsup_{\varepsilon \rightarrow 0} E(\mathbf{m}_{\varepsilon}) = E_0(m_{\parallel})$ , where  $\mathbf{m}_{\varepsilon} = (\sin \theta_{\varepsilon} \cos \phi_{\varepsilon}, \sin \theta_{\varepsilon} \sin \phi_{\varepsilon}, \cos \theta_{\varepsilon})$  and  $(\theta_{\varepsilon}, \phi_{\varepsilon})$  are as above.  $\square$

As an immediate consequence of  $\Gamma$ -convergence, we have the following asymptotic characterization of minimizers of the energy  $E_{\varepsilon}$  in terms of the minimizers of  $E_0$ .

**Corollary 7.** *Under the assumptions of Theorem 6, let  $\mathbf{m}_{\varepsilon} = (m_{\perp}^{\varepsilon}, m_{\parallel}^{\varepsilon}) \in H^1(\Omega; \mathbb{S}^2)$  be a sequence of minimizers of  $E_{\varepsilon}$ . Then, after extracting a subsequence, we have  $m_{\parallel}^{\varepsilon} \rightarrow m_{\parallel}^0$  and  $|m_{\perp}^{\varepsilon}| \rightarrow 0$  in  $L^1(\Omega)$ , where  $m_{\parallel}^0 \in BV(\Omega; \{-1, 1\})$  is a minimizer of  $E_0$ .*

We note that by classical results for problems with prescribed mean curvature (see, e.g., [33] and references therein), the minimizers of  $E_0$  are functions, whose jump set  $\Gamma \subset \overline{\Omega}$  is a union of finitely many  $C^{1,1}$  curve segments satisfying weakly the equation

$$\sigma_{wall} K(x) = 4h_{\parallel}^0(x), \quad x \in \Gamma \cap \Omega, \quad \Gamma'(x) \perp \partial \Omega, \quad x \in \Gamma \cap \partial \Omega, \quad (4.32)$$

where  $K$  is the curvature of  $\Gamma$ , positive if the set  $\Omega^+$  is convex, and the prime denotes arclength derivative. Physically, these are interpreted as the Dzyaloshinskii domain walls separating the domains of opposite out-of-plane magnetization under the external applied field. We also note that the limit energy  $E_0$  contains a contribution from the edge domain walls, which, however, is independent of the magnetization orientation near the edge and thus only adds a constant term to the energy.

**Remark 8.** We note that by the results of [31], we can also say that if  $m_{\parallel}^0$  is an isolated local minimizer of  $E_0$ , then there exists a sequence of local minimizers  $\mathbf{m}_{\varepsilon}$  of  $E_{\varepsilon}$  such that  $m_{\parallel}^{\varepsilon} \rightarrow m_{\parallel}^0$  and  $\mathbf{m}_{\perp}^{\varepsilon} \rightarrow 0$  in  $L^1(\Omega)$ .

Before concluding this section, let us comment on some topological issues related to the result in Theorem 6. We note that our upper construction in Theorem 6 uses the magnetization configurations that have topological degree zero. This has to do with the representation of the test configurations  $\mathbf{m}_{\varepsilon}$  adopted in the proof in terms of the angle variables  $(\theta_{\varepsilon}, \phi_{\varepsilon})$ , which are assumed to be of class  $C^1$  up to the boundary. Therefore, the proof does not immediately extend to the admissible classes with prescribed topological degree distinct from zero. This is not a problem, however, in view of the fact that away from the domain walls one could insert skyrmion profiles [36], suitably localized, into our test functions to prescribe a fixed topological degree for  $\varepsilon$  sufficiently small. Our result would then not be altered, in view of the fact that in the considered scaling the energy of a skyrmion is a lower order perturbation to that of chiral walls. In other words, under the considered scaling assumptions our energy does not see magnetic skyrmions.

## 5 Discussion

To summarize, we have analyzed the basic domain wall profiles in the local version of the micromagnetic modeling framework containing DMI, which is governed by the energy in (2.2). Specifically, we performed an analysis of the one-dimensional energy minimizing configurations on the whole line and on half-line and showed that the magnetization profiles expected from the physical considerations based on specific *ansätze* are indeed the unique global energy minimizers for  $|\kappa| < \sqrt{Q-1}$ . This is slightly below (about 30%) the threshold value of  $|\kappa| = \kappa_c = \frac{4}{\pi}\sqrt{Q-1}$ , beyond which helical structures emerge. Our methods rely on a sharp Modica-Mortola type inequality and do not extend to the narrow range of  $\sqrt{Q-1} \leq |\kappa| < \frac{4}{\pi}\sqrt{Q-1}$ . It is natural to expect that our result persists all the way to  $|\kappa| = \kappa_c$ , but to justify this statement one would need to develop new analysis tools for the vectorial variational problem associated with the domain walls.

Our one-dimensional analysis in section 3 identified two basic types of chiral domain walls: the interior and the edge domain walls. These one-dimensional domain wall solutions are the building blocks of the more complicated two-dimensional magnetization configurations in ultrathin films subjected to sufficiently small applied magnetic fields. This can be seen from the analysis of  $\Gamma$ -convergence of the energy in (4.2) performed in section 4. Either global or local energy minimizers for  $\varepsilon \ll 1$  may then be approximated by those of the energy in (4.3), which determines the geometry of the magnetic domains in the sample. Our findings indicate that in the considered limit the magnetization configurations solve the prescribed mean curvature problem in (4.32), again, for  $|\kappa| < \sqrt{Q-1}$ . We note that our variational setting could similarly be used to study the gradient flow dynamics governed by (4.2) (for a related study, see [42]). Other physical effects, however, need to be

incorporated to account for some unusual properties of chiral domain walls such as their tilt in sufficiently strong external fields [7, 40].

Finally, we would like to comment on the assumptions that lead to the model in (4.2), and on its possible generalizations. As was already mentioned, this energy functional is local, with the effect of the stray field surviving in the renormalized magnetocrystalline anisotropy term only. This is justified in the limit of arbitrarily thin ferromagnetic films [21]. In practice, this contribution is only the leading order term in the expansion of the energy in the film thickness for films whose thickness is less than the exchange length  $\ell_{ex}$  of the material. Going to higher order, two types of contributions appear. The first is the one coming from the sample boundary. In the limit of the dimensionless film thickness  $\delta = d/\ell_{ex}$  going to zero, this contribution becomes local and adds an extra penalty term for the in-plane component of the magnetization at the edge [30]:

$$E_{\varepsilon}^{edge}(\mathbf{m}) = \frac{\delta |\ln \delta|}{2\pi} \int_{\partial\Omega} (\nu \cdot \mathbf{m}_{\perp})^2 d\mathcal{H}^1(r), \quad (5.1)$$

where  $\nu$  is the outward unit normal to  $\partial\Omega$ . Here we took into account that in a perpendicular material the magnetic “charge” at the sample boundary would be smeared on the scale of  $\ell_{ex}$ . In the interior, the leading order contribution from the stray field energy beyond the shape anisotropy can be shown to be [28]:

$$E_{\varepsilon}^{bulk}(\mathbf{m}) = -\frac{\delta}{8\pi} \int_{\Omega} \int_{\Omega} \frac{(m_{\parallel}(\mathbf{r}) - m_{\parallel}(\mathbf{r}'))^2}{|\mathbf{r} - \mathbf{r}'|^3} d^2r d^2r' + \frac{\delta}{4\pi} \int_{\Omega} \int_{\Omega} \frac{\nabla \cdot \mathbf{m}_{\perp}(\mathbf{r}) \nabla \cdot \mathbf{m}_{\perp}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d^2r d^2r'. \quad (5.2)$$

Furthermore, for  $\delta = \lambda |\ln \varepsilon|^{-1}$  it was shown in the case  $\kappa = 0$  and periodic boundary conditions in the plane that as  $\varepsilon \rightarrow 0$  the effect of the stray field energy is to renormalize the one-dimensional wall energy to a lower value, as long as  $\lambda < \lambda_c = 2\pi\sqrt{Q-1}$  [28]. It is natural to expect from the results of [28] that, as  $\varepsilon \rightarrow 0$ , the wall energy for  $\kappa > 0$  will become

$$\sigma_{wall} = 4\sqrt{Q-1} - \pi\kappa - \frac{2\lambda}{\pi}. \quad (5.3)$$

Similarly, one would expect that in this regime the edge wall energy  $\sigma_{edge}$  would also be renormalized to minimize the sum of the exchange, anisotropy, DMI energies (all contained in (4.2)) and the stray field energy contributions from (5.1) and (5.2). This study is currently underway. At the same time, for  $\lambda > \lambda_c$  one expects spontaneous onset of multi-domain magnetization patterns and qualitatively new system behavior (for a recent experimental illustration, see [52]).
